A Modeling Approach to the Evaluation of Internal Sorting Methods<br>S. SITHARAMA IYENGAR**<br>and<br>DALE R. BARRETT*<br>Department of Computer Science, Jackson State University, Jackson, Mississippi 39217<br>Communicated by Arne Jensen

#### Abstract

The purpose of this paper is to report a modeling approach to the evaluation of internal sorting methods. The technique used is a regression modeling technique and has been found to be a very fast statistical method for evaluation which relies on the performance of data collection from the system being evaluated. The parameters considered for evaluation are: (1) number of stages, (2) number of transfers, (3) number of records, (4) sort time, ( 5 ) number of comparisons. The empirical model has been developed for sorting time as a function of the number of stages, number of records, number of comparisons, and number of transfers. The correlation coefficient obtained during the process of modeling was an average of 0.96 and has been found statistically significant.

## 1. INTRODUCTION

There has been much work going on to find efficient methods of sorting, since it is an important part of many large business data-processing problems.

Knuth [1] gives a detailed description of searching and sorting, and the algorithms described by him are simple but authoritative. He notes that sorting can be classified generally into internal sorting, in which the records are kept in the computer's high-speed random-access memory, and external sorting, when there are more records than can be held in memory at once. Internal sorting allows more flexibility in the structuring and accessing of the data, while external sorting shows us how to live with rather stringent accessing categories. The six different sorting techniques for our purpose are insertion sort, shell sort, quick sort, bubble sort, and tree sort. We shall present a little description of each of these sorting methods (for details see Ref. [1]):

[^0]Insertion sort. The items are considered one at a time, and each new item is inserted into the appropriate position relative to the previously sorted items. (This is the way many bridge players sort their hands, picking up one card at a time.)

Exchange sort. If two items are found to be out of order, they are interchanged. This process is repeated until no more exchanges are necessary.

Selection sort. First the smallest (or perhaps the largest) item is located, and it is somehow separated from the rest; then the next smallest (or the next largest) is selected, and so on.

Merge sort. Merging (or collating) means the combination of two or more ordered files into a single ordered file.

Distribution sort. Readers who are familiar with punched-card equipment are well aware of the efficient procedure used on card sorters, based on the digits of the keys; the same idea can be adapted to computer programming, and it is generally known as "radix sorting," "digital sorting," or "pocket sorting."

According to the above definitions the technique called in the previous report" "insertion sorting" is really a selection sort and will be so called in this report. The tree sort is considered a type of selection sort. The technique called selection sort previously is actually the shell-of-diminishing-increment sort. The shell sort procedure is a variation of the insertion technique. The bubble sort is considered one of the exchange procedures, as is the quick sort.

Algorithms for these five different procedures were obtained from D. E. Knuth and also from A. T. Berztiss [5]. Knuth suggests that the quick sort method could be enhanced if "subfiles of $M$ of fewer elements are left unsorted until the very end of the procedure, then a single pass of straight insertion is used to produce the final ordering." The algorithm for straight insertion was therefore used as a separate procedure as well as a procedure to be used in conjunction with quick sort. The remainder of the paper is organized as follows: general description of the model and its design, description of the input data to the model, calibration of the model, discussion of the results, model predictions, and conclusions.

## 2. GENERAL DESCRIPTION OF THE MODEL AND ITS DESIGN

A regression model [6,7] is considered as a fast statistical model of system performance which relies on the performance data collected from the system being evaluated. In view of the development of efficient algorithms described

[^1]in Knuth's book [1], an empirical model to evaluate the sort time as a function of number of stages, number of comparisons, number of transfers, and number of records will enhance the process of evaluation of internal sorting methods. Before we go into the formulation of the model, we shall discuss the system parameters: the number of stages, number of comparisons, number of transfers, and number of records. The number of stages is how many times the sort method must cycle before completion. The storage ratio is the ratio of the number of storage locations to the number of elements to be sorted. The number of transfers is an indication of the model's activity.

The model we are proposing in our paper will be of the following form:

$$
\begin{equation*}
\theta=f\left(N_{R}, D_{t}, N_{s}, N_{c}\right), \tag{1}
\end{equation*}
$$

where

$$
\begin{aligned}
\theta & =\text { sort time in sec, } \\
N_{R} & =\text { number of records }, \\
D_{t} & =\text { number of transfers }, \\
N_{c} & =\text { number of comparisons }, \\
N_{s} & =\text { number of stages } .
\end{aligned}
$$

The formulation process of the model is explained in Sec. 3.2.
The above functional relationship can be reduced to the following form after a multiple regression analysis:

$$
\begin{equation*}
\theta=C_{0}+C_{1} N_{R}+C_{2} D_{t}+C_{3} N_{s}+C_{4} N_{c} . \tag{2}
\end{equation*}
$$

This general model for all types of sort will be obtained after performing multiple regression analysis with $\theta$ as a dependent variable and $N_{R}, D_{t}, N_{s}$, and $N_{c}$ as independent variables. $C_{1}, C_{2}, C_{3}, C_{4}$ are regression coefficients, and $C_{0}$ is the intercept obtained after the multiple regression analysis. The model sorting-time equation can be expressed as a linear (log-log) function using the spss (Statistical Package for Social Science) program, which will be described in the next section of the paper. Then the equation (2) can be expressed in the following form:

$$
\begin{align*}
\log \theta=C_{0} & +C_{1} \log N_{R}+C_{2} \log D_{t} \\
& +C_{3} \log N_{s}+C_{4} \log N_{c} \tag{3}
\end{align*}
$$

or

$$
\begin{equation*}
\theta=e^{C_{0}+C_{1} \log N_{R}+C_{2} \log D_{1}+C_{3} \log N_{3}+C_{4} \log N_{\varepsilon}} . \tag{4}
\end{equation*}
$$

This equation can be used to find the sort time for any type of sort provided we know the variables $N_{s}, N_{c}, D_{t}$, and $N_{R}$.

### 2.1. CALIBRATION OF THE MODEL

The following definition used by Gomma [4] for the calibration of the model can be used in our study.

Calibration is basically an iterative procedure whose purpose is to reduce the difference in behavior between the model and the real system by adjusting the parameters of the model [4]. In the process of the calibration of the model, both stepwise and multiple regression analysis was done for each sort method using the log form of the data from Table 6 (excluding sort time as input).

## 3. PROGRAM DESCRIPTION AND GENERATION OF DATA

The sorting techniques (straight insertion, straight selection, bubble, shell, tree, and quick) were each written as subroutines in FORTRAN to be run on the music* system. The arguments for all six subroutines are $R$ and $N$ : the records and the number of records to be sorted.

The subroutine was tested using the program PSORT and printed these numbers. The program then had these numbers sorted by the subroutine being tested and printed by the terminal.

The processing time required by each subroutine to sort $100,200,500,1000$, 2000 , and 5000 records was determined with program COMSRT. The time was determined using the system subroutine tstime before and after calling on the tested subroutine. Unfortunately the system subroutine TSTIME reported time to only 0.01 seconds. This placed one limitation on the determination of the sorting time. The second limitation was the system limit of 180 seconds. Thus, the time for sorting 5000 records could not be obtained for the insertion, selection, and bubble sort subroutines. To obtain sorting statistics the program comsrt was altered to Gmsrt. For details ref. [3].

[^2]TABLE 1
Determination of Optimum Value of $M$ to be Used in the Quick-Sort Subroutine ${ }^{\text {a }}$

| No. of <br> Records | $M=1$ | $M=3$ | $M=5$ | $M=10$ |

| 5000 | 3.36 | 3.41 | 3.41 | 3.17 |

[^3]
### 3.1. DETERMINATION OF OPTIMUM $M$

The number of elements ( $M$ ) to be left unsorted at the end of the quick-sort subroutine had to be determined before accumulating any sorting data. To determine the optimum value of $M$, the sorting time was determined with values of $M$ set at $1,3,5$, and 10 for array sizes varying from 50 to 5000 records. Results were obtained for three runs at each value of $M$.

The average values for the three runs at each value of $M$ and array size are reported in Table 1. No advantage in sorting time is evident in Table 1 for any value of $M$. The value $M=1$ was used for all subsequent runs.

### 3.2. SORTING TIME AND SORTING STATISTICS

Three runs were made to determine the sorting time for each of the six sorting methods. The averages of the three runs are shown in Table 2.

Three runs were also made to determine the sorting statistics (processing time, number of stages, number of comparisons, and number of transfers) for each of the six sorting methods. The averages of the three runs are given in Tables 2 (sorting and processing time), 3 (number of stages), 4 (number of comparisons), and 5 (number of transfers). Wherever possible in these tables the results obtained by Iyengar and Ingram [2] are given for comparison.

It is evident in Table 2 that the sorting time is increased when sorting statistics are counted in the same run that sorting time is measured. These latter times should not be used as a measure of sorting time. It is also evident that the times reported by Iyengar and Ingram do not check with the results

*Average time in seconds. Each value shown is an average of three determinations.
${ }^{\text {b }}$ Exceeds 180 sec .
${ }^{c}$ Less than 0.01 sec .
obtained in this study for the selection, bubble, and shell sort, and are about the same as those obtained for the tree sort, but lower than those obtained for the quick sort.

The averages given in Table 2 are graphed in Fig. 1. Excellent linear (log-log) results are evident for the selection, insertion, and bubble sorts, with practically the same slopes and intercepts for all of them. The graphs for shell and tree sorts are the same and different from the other procedures. The lowest times are evident for the quick sort. Linearity ( $\log -\log$ ) is also evident for the shell, tree, and quick sorts, particularly for record sizes of 500 or greater. Thi poor resolution in sorting time ( 0.01 seconds) is probably responsible for the poor data obtained for array sizes of 200 and less.

## 4. INPUT DATA TO THE MODEL

This section describes how the data generated for all the parameters in Sec. 3 are used as the input data to the model. Table 6 shows the average value of three runs for each sorting method and the following parameters:
(1) Number of records sorted
(2) Sort time (in seconds)
(3) Number of stages
(4) Number of comparisons
(5) Number of data transfers

### 4.1. REGRESSION SUBMODEL TECHNIQUES

As described in the previous sections, it has been assumed that the amount of time required to sort a number of records can be expressed as a linear (log-log) function of the number of records, number of data transfers, number of stages, and number of comparisons. If true, this means that the sort time may be predicted by a linear regression submodel which is assumed to be of the form

$$
\begin{equation*}
\log \theta=C_{0}+C_{1} \log N_{R}+C_{2} \log D_{1}+C_{3} \log N_{s}+C_{4} \log N_{c}, \tag{5}
\end{equation*}
$$

where $\theta$ represents the sort time, $N_{R}$ the number of records, $N_{s}$ the number of stages, $D_{t}$ the number of data transfers, $N_{c}$ the number of comparisons, $C_{0}$ the intercept value, and $C_{1}, C_{2}$, and $C_{3}$ the regression coefficients of the parameters.

The linear regression analysis was done, and the regression submodel constructed, by using a standardized program developed for the Statistical Package for the Social Sciences (SPSS) language. spss is a packaged program specifically designed to compute those statistics typically used by social scientists. It was designed and developed in the late 1960s and is now one of the most widely used statistical packages.

The particular SPSS statistical subprogram used in this case was the subprogram regression, which can compute both step wise and multiple regressions. In the process of the calibration of the model, both stepwise and multiple regression analysis was done for each sort method using the log form of the data from Table 6 as input. The resulting submodels are shown in Tables 7-12 and figs. 2-4. Each submodel gives a very good fit to the data: the proportion of the variation explained ( $R^{2}$ ) for each is 0.94 or better.

### 4.2. MODEL PREDICTION

In order to examine the difference between the real system and the models, a comparison was done between the predicted sort time using the model equations and the observed sort time from Table 2. The results of these comparisons can be seen in Table 13. As the proportion of the variation explained by the model ( $R^{2}$ ) in each case was very good, we expected to find a close correlation between the actual and predicted times, and this was in fact the case. As can be seen from Table 13, the percentage differences between the actual times from Table 2 and the predicted times are quite small unless they represent a small number (less than 500) of records; and although the correlation increases with the number of records sorted, it is still quite good even at larger numbers of records. For instance, the percentage difference between the predicted time using the quick-sort regression submodel (Table 12) and the actual sort time is $0 \%$ at 50 records and increases only to $3.6 \%$ for 5000 records. Better results than those obtained for the shell sort, insertion sort, and

TABLE 13

|  | 1000 | 0.78 | 0.84 |
|  | 5000 | 4.91 | 6.07 |

selection sort would no doubt be possible but for the limitations described in Sec. 3 on the measurement of the sort time.

## 5. NOTE

Needless to say, the regression model presented herein is not complete. Possibly the most critical section is that dealing with model prediction. To our surprise, the model prediction was excellent. This is explained by the fact that the correlation coefficient obtained during the process of modeling was an average of 0.96 or better. It is possible that an empirical model such as the one developed in our paper would be useful in determining the type of sort to be used in data processing.

However, in the meantime we are considering the development of a hybrid model (regression and simulation model) for the classification and evaluation of internal sorting methods.

Fig. 2. Number of stages.

Fig. 3. Number of comparisons.

Fig. 4. Number of transfers.

## 6. CONCLUSIONS

This paper has described how a regression model for an internal sorting system may be constructed. By this means the advantages of regression techniques are exploited. Modeling by regression analysis provides a fast statistical method of modeling a system or a subsystem at a gross level.

A general model to compute the sorting time as a function of the number of stages, number of comparisons, number of transfers, and number of records has been presented in this paper, and a specific model for each of the six sorts (shell sort, insertion sort, tree sort, bubble sort, exchange sort, selection sort) to compute the sorting time has been presented. The correlation coefficient obtained during the process of modeling was an average of 0.96 and the predictions from the model are excellent.

Future endeavors to combine sımulation and regression modeling would add greatly to the models' value.

The authors would like to thank Professor Iyengar's graduate students, especially Mr. L. Pepper and Mr. W. Ingram, for contributing input data for the model; Dr. N. R. V. Murthy for his expert guidance on SPSS analysis of the data; and Dr. Jesse C. Lewis for his encouragement in this project.

Preliminary funding for this project was provided by the senior author.
